

Guelph's extender as compared to BL₁ significantly improved sow fertility after 3 days of storage (72.4 p. 100 versus 62.5 p. 100 for Guelph and BL₁, respectively ($p < 0.001$). Use of Guelph's extender might allow to preserve semen until 4 days after collection without any sudden decrease in fertility and prolificacy.

Fertility was significantly improved when using the total fraction of ejaculate instead of the rich one (67.9 p. 100 versus 60.7 p. 100) ($p < 0.02$). It was also significantly improved when using a strong dilution instead of a weak one (67.2 p. 100 versus 61.2 p. 100 for 30 and 120×10^9 spz/ml, respectively ($p < 0.05$).

The semen preparation technique now used in the French A.I. centres, i.e. collection of the total ejaculate fraction diluted in Guelph's extender and split into ready-to-use doses of 100 ml therefore seems to be fitted for obtaining a maximum fertility.

Changes in the body composition of nulliparous sow during the reproductive cycle : effect of the dietary protein level during gestation

Centre de Rennes-Saint-Gilles, F 35590 L'Hermitage*

An experiment was made on 40 nulliparous *Large White* sows distributed into 2 groups according to the protein level of the gestation diet (2 kg per day of a diet containing 10 or 14 p. 100 protein). During lactation, the animals received a diet containing 14 p. 100 protein according to a daily feed supply of 5.1 kg.

In each group we compared the body composition of the animals at different physiological stages (non-pregnant, post-partum, lactating, post-weaning) and for an equivalent carcass weight (118 kg), except during lactation (103 kg).

The measures performed involved the composition of half carcass cuts, either muscle rich (loin, ham) or fat rich (backfat, leaf fat), determination of the specific gravity of ham and loin + backfat measurement of backfat thickness at different sampling sites and of the eye muscle area (at the level of the 13th rib). The physical characteristics of the meat were tested by determination of pH in 3 muscles, 45 minutes and 24 hours after slaughter and by measurement of the water binding capacity.

At farrowing, the rise in the protein supply during gestation increased the muscle mass at the expense of the fat mass (loin in p. 100 of net weight : 30 to 32.7; eye muscle area, cm² : 37.9 to 39.6; loin + backfat specific gravity : 1.029 to 1.047). This increase was not observed in non pregnant sows in which the fat content tended to increase with the largest protein supply (backfat : p. 100 weight : 14.8 - 17.15; specific gravity of eye muscle : 1.035 to 1.031). Accordingly, only a dietary protein level of 14 p. 100 led to a larger muscle deposition in pregnant sows as compared to non pregnant sows.

During lactation (at 21 days) a large mobilization of muscle masses was observed in the sows of the 2 groups (eye muscle area cm², at 14 p. 100 protein : from 39.6 to 31.0; at 10 p. 100 protein : from 37.9 to 26.3); fat deposition was only affected in the group receiving 10 p. 100 protein during gestation (side backfat thickness : from 32 to 26.4 cm).

The effect of the gestation diet on the body composition of the animals was also noticed after weaning.
