(Received 17 July 1990; accepted 13 October 1990)

Summary — The motor activity of five dogs was recorded in three different experimental situations: A: free access to food and water during a 12:12 LD cycle; B: free access to food and water during constant lighting; C: a single meal per 24 hours at a set time during a 12:12 LD cycle. This study was designed to determine the possible influence of the two synchronizers (light-dark cycle, single daily meal) on the duration and pattern of motor activity in these five dogs over 24 h. The motor activity of all five dogs in situation A was predominantly diurnal. In situations B and C, the duration and pattern of motor activity over 24 hours were modified in a divergent manner. The motor activity of dog 1 was not influenced by the single daily meal synchronizer. By contrast, the motor activity of dog 3 was not influenced by the light-dark cycle synchronizer. In the three other dogs, the two synchronizers had a similar influence, but differed in intensity. No common pattern of sensitivity to the two synchronizers was observed for these five animals. Each subject had its own specific reactivity and sensitivity that could only be determined by individual observations.

motor activity / light-dark cycle / constant light / food availability / food intake / dog

Résumé — Influence de deux synchroniseurs sur l'activité motrice du chien en semi-liberté.

L'activité motrice de 5 chiens a été enregistrée dans 3 situations expérimentales :

- situation A: alimentation ad libitum, en cycle LD 12:12;
- situation B: alimentation ad libitum en éclairage continu LL;
- situation C: un repas à heure fixe par 24 h en cycle LD 12:12.

Le but du travail était de rechercher l'influence éventuelle des 2 synchroniseurs, alternance L/D et alimentation à heure fixe, sur la durée et la répartition dans les 24 h de l'activité motrice de ces 5 chiens.

En situation A, tous les chiens ont une activité motrice à prédominance diurne. En situation B et C, la durée et la répartition, dans les 24 h, de l'activité motrice sont modifiées de façon divergente chez les 5 chiens. L'activité motrice du chien 1 est influencée par le synchroniseur alternance L/D. A l'opposé, l'activité motrice du chien 3 est surtout influencée par le synchroniseur repas à heure fixe. Chez les 3 autres chiens, on observe une influence conjointe mais d'importance variable des 2 synchroniseurs.

En définitive, il n'est pas possible de proposer un modèle commun décrivant la sensibilité de ces 5 chiens aux 2 synchroniseurs étudiés. Chaque individu présente une réactivité et une sensibilité qui lui sont propres et ne peuvent être connues que par l'observation individuelle.

activité motrice / cycle jour–nuit / lumière constante / consommation alimentaire / chien

INTRODUCTION

Numerous studies performed under *ad libitum* conditions have demonstrated that motor activity and food intake in certain species such as rat (Hunt *et al*, 1939; Finger, 1951; Kayser, 1978; Armstrong *et al*, 1980; Rosenwasser *et al*, 1981) and hamster (Aschoff *et al*, 1973; Zucker and Stephan, 1973) are essentially nocturnal, whereas in other species such as monkey (Sulzman *et al*, 1977) and dog (O'Connor and Potts, 1969; Ganz and Kappen, 1980) such behavior is especially diurnal. The light-dark (LD) cycle is a strong synchronizer of the circadian rhythm of food intake and motor activity in most of these animals. Under free running conditions, the spontaneous rhythms of food intake and motor activity generally exhibit a period greater than 24 hours. This has been observed for the rat (Boulos *et al*, 1980; Rosenwasser *et al*, 1981), the hamster (Aschoff *et al*, 1973) and the monkey (Sulzman *et al*, 1977).

In the absence of a light-dark cycle, it has been shown that other factors can entrain the circadian rhythm of motor activity. Under constant light (LL), periodic presentation of food is a strong synchronizer of motor activity in rat (Edmonds and Adler, 1977; Rosenwasser *et al*, 1981) and monkey (Sulzman *et al*, 1977). Interaction of the light-dark synchronizer and the periodic food access synchronizer on motor activity in the rat has been studied by several authors. While animals were generally subjected to a 12:12 LD cycle and had access to food at a preset time during the light phase, results varied. For Gibbs (1979) and Edmonds and Adler (1977), the rat almost completely inverts its motor activity pattern when it has access to food during the light phase. By contrast, Coleman *et al* (1982) showed that this animal conserves its motor activity in the dark

phase, although this author did note anticipatory spurts of activity before meals, as reported by Boulos and Terman (1980). Few studies (Mugford, 1977; Ardisson *et al*, 1981; Ganz and Kappen, 1980) have been carried out on the dog, and, to our knowledge, none has specifically investigated the interaction of these two synchronizers on the motor activity of this animal.

We previously described three types of drinking behaviour dependency on both light-dark alternation and meal timing in the dog (Ozon *et al*, 1987). The present study was designed to study the respective influence of these two synchronizers on the duration and pattern of motor activity over 24 hours in the dog. This study was carried out on the same five animals to identify any possible convergent reactions of the two behaviours (Ozon *et al*, 1987).

MATERIALS AND METHODS

Five dogs were studied (1: male mongrel, 8 years old, weighing 18 kg; 2, female mongrel, 6 years old, weighing 23 kg; 3: male mongrel, 6 years old, weighing 22 kg; 4: female beagle, 5 years old, weighing 15 kg; 5: male beagle, 6 years old, weighing 16 kg). During the experiment, each animal was housed in a 30 m² room at a constant temperature (22 °C ± 2 °C) and a relative humidity of 60% ± 10%. The room was lit artificially from 7 00 to 19 00 h (12 h). Intake of water and food was noted continuously, as described previously (Ardisson *et al*, 1981). Dogs were fed with a dry preparation (UAR 121). Motor activity was recorded continuously by a Doppler radar system. The recording shape allowed body movements to be distinguished from walking activity which is only held for measuring motor activity. Short periods of still standing included in walking activity were also recorded.

Each dog was studied in three situations:

Situation A: free access to food and water; light phase from 7 00 to 19 00 h (12:12 LD). Results were used to assess the evolution of hour-

ly means for motor activity and food intake over 24 h.

Situation B: free access to food and water with constant lighting; same measurements as in situation A.

Situation C: access to food limited to between 18 30 and 19 00 h every day; lighting from 7 00 to 19 00 h (12:12 LD). Results were used to determine the hourly means for motor activity of each dog over a 24-h period.

Situations A, B and C were separated by approximately 15 months. Animals were returned to their kennels between experiments. Each situation was distributed at random over the year to avoid any possible seasonal influences. All of the experiments were performed between May 1980 and March 1984. Dogs were first weighed according to a previously described protocol (Ardisson *et al*, 1981). During all the experiments, weight variation never exceeded 5% in all five animals.

Before beginning situations B or C, the dogs were placed in situation A for 7 d to verify the stability of their food intake behavior and body weight. These 7 d were not included in the results.

Data obtained in these experiments were used to calculate: the mean daily motor activity (min) of each dog (\pm SEM); evolution of the mean motor activity (min) over 24 h in situations A, B and C (\pm SEM); the mean daily food intake (g) of each dog (\pm SEM); evolution of the mean food intake (g) over 24 h in situations A and B (\pm SEM).

One-way analysis of variance (ANOVA) was used for statistical comparison of the different situations.

RESULTS

Situation A

Food intake

Analysis of mean hourly food intake over 24 h revealed that three dogs essentially ate during the light phase (fig 1). Dog 1 ate its daily food ration exclusively during the light phase. Dogs 4 and 5 had similar food

intake behaviors; they ingested 85% (4) and 84% (5) of their total intake during this phase. Dogs 2 and 3 ate their daily food ration during the entire 24 h period, and the amounts ingested were slightly larger (12 to 20%) during the day than at night (table I). The maximum hourly food intake periods for all five dogs occurred during the light phase (fig 1). Two dogs exhibited maximum food intake at the beginning of this phase (1 and 5 at 7 00 h), while two others had their maximum in the middle of this phase (3 at 13 00 h and 4 at 11 00 h). Maximum food intake for the last dog occurred during the second half of the light phase (2 at 18 00 h).

Motor activity

As shown by the mean hourly figures for motor activity over 24 h, the motor activity of all five dogs was essentially diurnal (fig 2). Diurnal activity represented 87% (1), 63% (2), 68% (3), 78% (4) and 70% (5) of the total daily activity (table II).

Maximum motor activity for four of the dogs occurred during the first hour of the light phase (dogs 2, 3, 4, 5). Maximum activity for dog 1 occurred two hours after the start of the light phase. For dogs 2, 3, 4 and 5, motor activity remained at a mean level during the remainder of the light phase, then decreased in the dark phase, but never dropped to zero. Only dog 1 showed a decline in activity beginning at 15 00 h (fig 2).

Food intake and motor activity

Activity in dogs 1, 4 and 5, who ate most of their food during the light phase, was also essentially diurnal. However, in these three animals, the proportion of activity in the light phase was always slightly lower than the proportion of food ingested during this phase. By contrast, in dogs 2 and 3, the

proportion of diurnal activity was superior to the proportion of food ingested during this same phase.

Situation B

Food intake

Comparison of food intake during constant lighting and during a light-dark cycle (table I) warrants several observations: dog 1 ate

a supplementary amount of food between 7 00 h and 19 00 h that increased its 24 h total food intake in a highly significant manner; dog 2 modified its food intake pattern over 24 h, but the total amount ingested per day remained the same as in situation A (table I); dog 3 conserved the same eating pattern and the total amount of food ingested per day did not differ significantly from that in situation A (table I); dogs 4 and 5 maintained approximately the same patterns, although they significantly re

duced their food intake. This reduction was most marked in dog 5 (table I).

Motor activity

When the mean 24 h durations of motor activity in constant lighting are compared to those during the LD cycle (table II), several observations can be made: motor activity in dogs 1, 2 and 5 increased by

24% to 55%. This increase was significant for dog 1. It occurred especially between 19 00 h and 7 00 h for all three dogs. It was accompanied by marked levelling in the hourly activity pattern for dogs 2 and 5. By contrast, data for dog 1 revealed only a prolongation of the mean activity period between 16 00 h and 19 00 h (fig 2); motor activity in dog 4 decreased very significantly over 24 h, especially between 7 00 h and 19 00 h. This led to a very clear damp-

ing of its hourly motor activity pattern (fig 2); the 24 h motor activity duration of dog 3 remained identical to that in situation A. The pattern of this motor activity remained the same for 24 h (table II, fig 2).

Food intake and motor activity

Comparison of total daily food intake and the amount of daily motor activity in situations A and B reveals that three dogs exhibited parallel evolutions in their food intake and motor activity. Under constant lighting, dog 1 increased both its food intake (+ 29%) and its motor activity (+ 55%), dog 4 simultaneously reduced its food intake (– 22%) and motor activity (– 48%), and dog 3 did not modify either its food intake or motor activity. Different evolutions were noted for the other two dogs. Under constant lighting, dog 2 modified its hourly food intake pattern (fig 1), but there was no change in the total amount ingested per day; by contrast, the duration of this animal's mean daily motor activity increased (+ 24%), although in a non-significant manner, except from 19 00 h to 7 00 h. For dog 5, eating behavior and motor activity evolved in opposite ways: reduction in food intake (– 37%) and increase in daily motor activity (+ 29%).

In short, elimination of the LD synchronizer produced both convergent and diver-

gent modifications in eating behavior and motor activity of these five dogs. Only the food intake behavior and motor activity of dog 3 were independent of this synchronizer.

Situation C

Food intake

Dogs 2 and 4 ingested an amount of food equivalent to that in situation A in a single meal (table I). By contrast, animals 1, 3 and 5 significantly reduced their daily food intake by 23% to 44% (table I).

Motor activity

The mean hourly motor activity profiles for all 5 dogs were fairly similar to those in situation A, except from 18 00 h to 20 00 h. When only a single meal was given between 18 30 h and 19 00 h, the duration of motor activity in all dogs increased from 18 00 h to 20 00 h (fig 3). This increase represented 6% to 12% of the total daily activity in situation C (table II).

Mean daily levels of motor activity evolved in various ways: dog 1 did not significantly modify its mean daily motor activity duration; dogs 2 and 3 significantly decreased this duration, by 27% and 45% respectively. This decrease occurred

equally in the light and dark phases; dogs 4 and 5 strongly increased their daily motor activity (by 57% to 71%). This increase was relatively higher during the dark phase.

Food intake and motor activity

Only one animal (dog 3) presented a parallel evolution in its food intake and motor activity, which were reduced significantly. The other two dogs that also reduced their

food intake (1 and 5) exhibited either no significant modification in activity (1) or a significant increase in motor activity (5). The dogs that ate the same amount of food as in situation A (2 and 4) displayed opposite evolutions in their motor activity: motor activity decreased significantly in dog 2 but increased markedly in dog 4.

In summary, four dogs (2, 3, 4, 5) significantly modified (increased or decreased) their motor activity when access to food

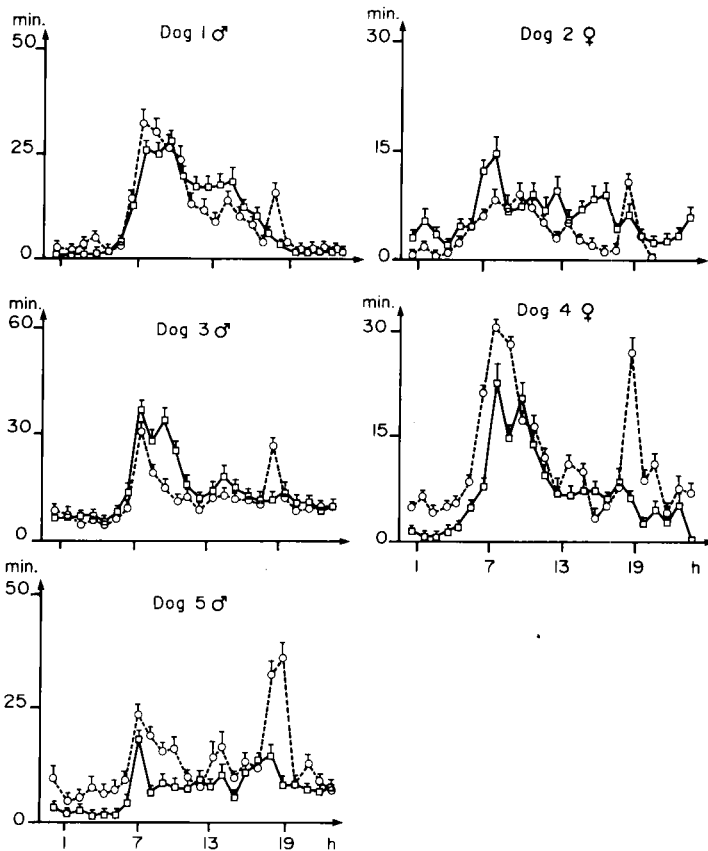

Fig 3. Mean hourly motor activity (+ SEM) for five dogs. The curves (—□—□—) show an average of 19 (dogs 2 and 3), 20 (dogs 1 and 5) and 21 (dog 4) observation days in situation A. Meal between 18 30 h and 19 00 h, in situation C.

was limited to half an hour every 24 hours. Only dog 1 failed to show any significant modification in motor activity compared to situation A.

DISCUSSION

Regardless of the protocol considered, this study provides further evidence for the existence of marked inter-individual differences. These differences were most marked in situations B and C. They are noted even in same race dogs, for instance, dogs 4 and 5 were very similar in situation A, but reacted in a very different manners in the two other experimental situations. Moreover, no two identical patterns of evolution were ever seen in situations B and C for the five dogs. Such inter-individual variability is not specific to the dog species. It has also been observed in the rat. Several authors (Richter, 1927; Hunt and Schlosberg, 1939; Finger, 1951; Edmonds and Adler, 1977; Gibbs, 1979) have observed different eating behavior and motor activity from one subject to another when individual data is analyzed.

Measurement of motor activity in situation A confirmed that the dog belongs to those species with predominantly diurnal behavior (Mugford, 1977; Ganz and Kappen, 1980) as opposed to such nocturnal species as the rat (Richter, 1927; Hunt and Schlosberg, 1939). All five dogs concentrated more than 60% of their activity in the light phase (87% for dog 1).

Suppression of the light-dark cycle was followed by an increase in motor activity for dogs 1, 2 and 5. For all of these three dogs, this increase occurred especially during the phase corresponding to the dark phase in situation A. These results suggest that the light-dark cycle is a synchronizer of motor activity variations, and

that the dark had a more or less intense inhibitory action on these three animals.

The motor activity of dog 4 was very different from that of dogs 1, 2 and 5 under constant light conditions. The hypothesis of an inhibitory effect of the dark phase on activity is not applicable for this animal. The endogenous rhythm at the origin of motor activity variations was weak in this animal. By contrast, the light-dark cycle was both a very active synchronizer of this rhythm and a strong stimulant of the level of activity.

The responses are very different for two female dogs (2 and 4), indicating that sex is not a determinant factor.

Dog 3 showed no significant modification in its motor activity under constant lighting. In this animal, variations in the level of motor activity were determined by a very strong endogenous rhythm which was not influenced by the light-dark cycle synchronizer under the experimental conditions.

In all the five dogs, the single daily meal was accompanied by a transient increase in motor activity in the hour in which food was ingested and, to a lesser degree, in the succeeding hour. This motor activity peak linked to food intake always represented only a small fraction of the animals' total daily activity. No motor activity peak was observed in any of the five dogs in the hours preceding food intake, as has been described in the rat. In this last species, numerous authors (Edmonds and Adler, 1977; Rosenwasser *et al*, 1981; Coleman *et al*, 1982) have reported supposedly "anticipatory" activity before meals when feeding is restricted to once or twice per 24 hours. Likewise, none of the five animals displayed any post-feeding activity comparable to that described in the dog by Ganz and Kappen (1980). Reduction of the average daily activity in two on the dogs (2

and 3) suggests that the single meal had an inhibitory effect on their motor activity. The synchronizing effect of the single meal was not very strong in these two dogs, because the relative distribution of motor activity between the light and dark phases remained similar to that during control situation A. By contrast, dogs 4 and 5 showed a strong increase in their motor activity, particularly in the dark phase. For these two animals, the daily single meal was a strong stimulant of activity and a synchronizer whose action was stronger than in the two previous dogs. Finally, only one dog (1) seemed to be insensitive to the single daily meal synchronizer. The degree of independence appears very large because modifications of food intake were very marked in this situation. Indeed, this animal ate only one meal a day instead of the average of three in situation A, and it ingested only 75% of its usual daily intake.

CONCLUSION

Situations B and C led to behavioral modifications that were very different from one subject to another. Analysis of all motor activity data reveals that the respective influences of the two synchronizers were variable from one animal to the other. In dog 1, the single meal time synchronizer had no significant influence under experimental conditions. In dog 3, the light-dark cycle did not appear to have any significant influence. Dogs 2 and 5 were highly affected by the feeding time synchronizer but relatively less so by the light-dark cycle synchronizer. However, in these two animals, the feeding time had opposite effects on the average duration of motor activity. Finally, only dog 4 was sensitive to both synchronizers in a comparable way.

Overall, this study confirms the interest of individual studies (Richter, 1927; Hunt

and Schlosberg, 1939; Finger, 1951; Edmonds and Adler, 1977; Gibbs, 1979) in addition to population studies. Data obtained for the two synchronizers did not permit identification of any reactivity pattern common to all five dogs. Each subject presented a specific reactivity and sensitivity that can only be determined by individual observations.
